ABSTRACT

Complex organic molecules (COMs) have been observed not only in the hot cores surrounding low- and high-mass protostars, but also in cold dark clouds. Therefore, it is interesting to understand how such species can be formed without the presence of embedded energy sources. We present new laboratory experiments on the low-temperature solid state formation of three complex molecules – methyl formate (HC(O)OCH₃), glycolaldehyde (HC(O)CH₂OH) and ethylene glycol (H₂C(OH)CH₂OH) – through recombination of free radicals formed via H-atom addition and abstraction reactions at different stages in the CO→H₂CO→CH₃OH hydrogenation network at 15 K. The experiments extend previous CO hydrogenation studies and aim at resembling the physical–chemical conditions typical of the CO freeze-out stage in dark molecular clouds, when H₂CO and CH₃OH form by recombination of accreting CO molecules and H-atoms on ice grains. We confirm that H₂CO, once formed through CO hydrogenation, not only yields CH₃OH through ongoing H-atom addition reactions, but is also subject to H-atom-induced abstraction reactions, yielding CO again. In a similar way, H₂CO is also formed in abstraction reactions involving CH₃OH. The dominant methanol H-atom abstraction product is expected to be CH₂OH, while H-atom additions to H₂CO should at least partially proceed through CH₃O intermediate radicals. The occurrence of H-atom abstraction reactions in ice mantles leads to more reactive intermediates (HCO, CH₃O and CH₂OH) than previously thought, when assuming sequential H-atom addition reactions only. This enhances the probability to form COMs through radical-radical recombination without the need of UV photolysis or cosmic rays as external triggers.

1 INTRODUCTION

CO is the second most abundant molecule in the interstellar medium (ISM) after H₂ (Ohishi, Irvine & Kaifu 1992). It is formed in the gas phase and despite its high volatility, carbon monoxide accretes on the surfaces of grains in the dense and cold parts of molecular clouds. After water, CO is the second most abundant component of interstellar ices (Pontoppidan 2006). Observational data show that rather than mixing with H₂O, the bulk of the CO accretes on top of a previously formed H₂O-rich polar ice, forming an apolar CO-rich ice layer (Tielens et al. 1991, Öberg et al. 2011a; Boogert & Ehrenfreund 2004; Gibb et al. 2004; Mathews et al. 2013, Boogert, Gerakines & Whittet 2015). The resulting CO-coating, in turn, is thought to react with impacting H-atoms, producing H₂CO via the HCO intermediate radical and subsequently CH₃OH through CH₃O

or, possibly, CH₂OH radical intermediates. This surface formation route is generally considered to be the chemical pathway explaining the observed abundance of methanol in dense clouds, both in the solid state and in the gas phase. The process has been subject of numerous experimental (Hiraoka et al. 1994; Zhitnikov & Dmitriev 2002; Watanabe & Kouchi 2002; Fuchs et al. 2009), theoretical and modelling (Tielens & Hagen 1982; Shalabiea & Greenberg 1994; Cuppen et al. 2009, Vasyunin & Herbst 2013) studies. For a recent review, see also Linnartz, Ioppolo & Fedoseev (2015). Moreover, combined laboratory and observational data show that CO and CH₃OH are intimately mixed in interstellar ices. This is fully consistent with a common chemical history (Cuppen et al. 2011).

Solid methanol, in turn, has been proposed as a starting point for the formation of complex organic molecules (COMs). Experiments involving energetic processing, e.g., UV photolysis (Öberg et al. 2009; Henderson & Gudipati 2015), soft X-ray irradiation (Chen et al. 2013), high-energy electron (Bennett et al. 2007; Maity,

* E-mail: chuang@strw.leidenuniv.nl

Kaiser & Jones 2015) and ion (Moore, Ferrante & Nuth 1996; de Barros et al. 2011) bombardment, and low-energy electron radiolysis (Boamah et al. 2014) of solid methanol ice, show that COMs form upon recombination of dissociation products. This is in line with a number of astronomical observations (for recent reviews see Herbst & van Dishoeck 2009; Caselli & Ceccarelli 2012). However, these experiments do not explain the recent detection of COMs in dark clouds where icy grains are not exposed to strong UV fields or have been heated. In particular, methyl formate, acetaldehyde, dimethyl ether and ketene have been detected in the cold pre-stellar core L1689B (Bacmann et al. 2012). The same species have also been seen in the cold pre-stellar core B1-b (Cernicharo et al. 2012), in the cold outer envelopes of low-mass protostars (Öberg et al. 2010), and in outflow spots in dark clouds where the ice mantles are liberated by shocks (Arce et al. 2008; Öberg et al. 2011b). Acetaldehyde and ketene were also detected in the cold pre-stellar core L1544 (Vastel et al. 2014). These observations clearly hint for a scenario in which COMs also form at temperatures below 15 K. Recent work by Fedoseev et al. (2015) demonstrated *non-energetic* routes to form COMs by surface hydrogenation of CO molecules.

An efficient pathway, creating a C–C backbone without the involvement of energetic processing, has the potential to form COMs earlier than expected during the chemical evolution of interstellar clouds and moreover will increase the chemical diversity. The solid state formation of various two- or even three-carbon bearing species was already suggested in a number of astrochemical models. Charnley, Rodgers & Ehrenfreund (2001) and Charnley & Rodgers (2005) studied C-atom addition reactions to HCO and HCCO radicals, whereas Garrod, Weaver & Herbst (2008) and Woods et al. (2012) worked on a backbone extension through recombination of various carbon-bearing intermediates, such as CH₃, HOCO and the CO hydrogenation intermediates; HCO, CH₃O and CH₂OH. Some of these reactions were already proposed quite some time ago, i.e., by Agarwal et al. (1985) and Schutte (1988), to explain results obtained after energetic processing of ices. Up to now, however, experimental studies verifying the formation of COMs along non-energetic pathways have been largely lacking, with exception of the above-mentioned study by Fedoseev et al. (2015) who showed that glycolaldehyde (HC(O)CH₂OH) and ethylene glycol (H₂C(OH)CH₂OH) form at low temperatures in CO+H deposition experiments. In their study, Fedoseev and co-workers combined molecule specific desorption temperatures and ionization fragmentation patterns for the newly formed species to conclude that recombination of HCO radicals yields glyoxal (HC(O)CHO) that is subsequently converted to glycolaldehyde and ethylene glycol upon two or four consecutive H-atom additions, respectively. They also suggested a possible formation route of methyl formate (HC(O)OCH₃) through recombination of HCO and CH₃O radicals, but it was not possible to experimentally confirm this.

The concept of non-energetic H-atom abstraction reactions is not new. Tielens & Hagen (1982) presented modelling calculations that emphasized the importance of H-atom abstraction reactions in grain-surface hydrogenation sequences. Experimental work by Nagaoka, Watanabe & Kouchi (2005) investigated the exposure of methanol ice to D-atoms. They found that partially deuterated methanol (CH₂DOH, CHD₂OH and CD₃OH) is quickly formed upon D-atom exposure of solid CH₃OH at 10 K. Following results from ab initio calculations, the authors proposed that one of the possible H–D substitution pathways takes place via H-atom abstraction from the methyl side of methanol to form the hydroxymethyl radical (CH₂OH), after which D-atom addition forms CH₂DOH.

Subsequently, Hidaka et al. (2009) proposed H–D substitution in H₂CO to also originate from an H-atom abstraction yielding HCO followed by D-atom addition to form HDCO. In both studies, the existence of abstraction reactions is crucial to explain the formation of deuterated molecules. Similar H-atom abstraction reactions may be triggered by H-atoms as well, i.e. instead of D-atoms, which would effectively increase the total amount of HCO, CH₃O and CH₂OH radicals formed in the ice, increasing the probability that recombination reactions result in COM formation.

The aim of this study is to verify the formation of COMs through H₂CO+H and CH₃OH+H, extending on Fedoseev et al. (2015) by focusing on the influence of H-atom induced abstraction reactions along with H-atom addition events. We experimentally investigate hydrogenation of pure ice samples (H₂CO or CH₃OH) as well as ice mixtures (H₂CO+CO, CH₃OH+CO, or H₂CO+CH₃OH). Both the existence of abstraction reactions involving H₂CO and CH₃OH and the possible formation of COMs are discussed. Special care is taken to verify that the COMs are products formed during codeposition, and not the result of thermally induced chemistry upon heating or due to contaminations.

2 EXPERIMENTAL PROCEDURE

2.1 Description of the setup

All experiments are performed under ultra-high vacuum (UHV) conditions, using the SURFRESIDE² setup that has been described in detail by Ioppolo et al. (2013). This setup consists of three distinct UHV chambers: a main chamber with base pressure of $\sim 10^{-10}$ mbar and two beam line chambers with base pressures in the range of 10^{-9} – 10^{-10} mbar. These chambers are separated by shutters, allowing independent operation of the individual parts. In the main chamber, a rotatable gold-coated copper substrate is mounted on the tip of a cold head of a closed-cycle helium cryostat. Accessible temperatures range from 13 to 300 K and ice samples are deposited on the substrate with monolayer precision (where 1 ML is assumed to be $\sim 1 \times 10^{15}$ molecules cm⁻²). The absolute temperature is accurate to better than 2 K, while the relative precision is better than 0.5 K.

The beam line chambers comprise different atom sources: a Hydrogen Atom Beam Source (HABS, Dr. Eberl MBE-Komponenten GmbH; see Tschersich 2000) generating H- or D-atoms by thermal cracking H₂ and D₂, and a Microwave Atom Source (MWAS, Oxford Scientific Ltd; see Anton et al. 2000) capable of producing H-, D-, O-, or N-atoms as well as various radicals by cracking selected parent molecules in a capacitively coupled microwave discharge (275 W at 2.45 GHz). Here only the MWAS is used, as the HABS chamber may contain CO contaminations when operated at high temperatures of the tungsten filament. Typical atom fluxes amount to roughly 6×10^{14} atoms min⁻¹ cm⁻². Along the path of both beam lines, a nose-shape quartz pipe is placed behind the shutter to efficiently quench excited atoms and non-dissociated molecules through collisions with the wall of the pipe. In addition, two separate dosing lines in the main chamber are used for deposition of molecular components of the ice, i.e. CO, H₂CO and CH₃OH. The individual gas samples are prepared by introducing single gases into a distinct well prepumped ($< 1 \times 10^{-4}$ mbar) full-metal reservoir. By means of a high-precision full-metal leak valve gas vapours are introduced into the UHV chamber with normal and 68° incidence angles to the sample. Degassed liquid CH₃OH (Sigma-Aldrich 99.9 per cent) is used to obtain CH₃OH vapour and solid

3.3	H ₂ CO+CH ₃ OH	15	1:0.1	16 × 10 ¹³	2 × 10 ¹³	–	50				

Note. All of the relative abundances are based on values in Fig. 7.

^aThese values are obtained after subtraction of the control experiment accounting for the influence of thermal processing of the ice and contaminations (i.e. red columns in the upper panel of Fig. 7).

paraformaldehyde powder (Sigma-Aldrich 95 per cent) warmed to 60–80°C under vacuum to generate H₂CO vapours. Residuals are typically shorter oligomers of formaldehyde and water. A CO gas cylinder (Linde 2.0, residuals: ¹³CO, N₂ and CO₂) is used for the preparation of carbon monoxide containing ice samples.

The ice diagnostics are performed by using either Fourier transform infrared absorption spectroscopy (FT-RAIRS) or temperature-programmed desorption quadrupole mass spectrometry (TPD QMS). The first method allows *in situ* studies of species embedded, formed or consumed in the ice, but has limited sensitivity and selectivity. The FT-RAIRS covers the range between 4000 and 700 cm⁻¹ with a spectral resolution of 1 cm⁻¹. A modified Lambert–Beer’s law is used to derive number densities of CO and H₂CO on the substrate using absorbance strength as described in Ioppolo et al. (2013). The absorbance strength values of CO, CH₃OH and H₂CO are obtained from transmission absorbance strength values as described by Watanabe et al. (2004). After completion of a codeposition and RAIRS experiment, a TPD QMS experiment is performed with a typical rate of 5 K/min to monitor thermally desorbing ice species. The TPD QMS is a more sensitive technique and combines known desorption temperatures with dissociative ionization frag-

mentation patterns upon electron impact in the head of the QMS. This makes it a strong diagnostic tool to recognize newly formed species, but obviously this technique comes with the thermal processing and ultimately destruction of the ice. See also Ioppolo, Öberg & Linnartz (2014) and Linnartz, Ioppolo & Fedoseev (2015) for further technical details.

2.2 Experimental methods

Three distinct sets of experiments are performed and systematically listed in Table 1. Each of them addresses a specific goal.

1) Verification of CO and H₂CO formation by H-atom abstraction from H₂CO and CH₃OH, respectively; exps 1.1–1.11.

H-atom-induced abstraction reactions from H₂CO and CH₃OH yielding CO and H₂CO, respectively, are verified by codepositing pure H₂CO or CH₃OH samples and H-atoms for different settings. The applied codeposition technique has the advantage that penetration depth issues into the bulk of the ice can be circumvented, as

two or more species can be deposited simultaneously rather than sequentially. The latter has been a problem in previous pre-deposition experiments (Watanabe, Shiraki & Kouchi 2003; Fuchs et al. 2009) in which only the top few layers were involved in H-atom-induced reactions. In a codeposition experiment, gas mixing ratios are easily varied and the consequent use of a high enough abundance of H-atoms compared to the molecules of interest guarantees that they all become available for encounters with H-atoms. Moreover, the formed products are trapped in the growing ice lattice and this prevents them from further interactions with H-atoms. Furthermore, codeposition mimics the actual processes taking place on an interstellar grain in space when the outer layer starts accreting CO molecules together with impacting H-atoms (Cuppen et al. 2009).

The newly formed species are monitored *in situ* for the full time of a 360 min codeposition experiment by means of RAIRS. After completion of the codeposition, a TPD QMS experiment is performed. Control experiments comprise pure H₂CO and CH₃OH depositions without H-atoms (exps 1.2 and 1.6), H-atom deposition without H₂CO or CH₃OH molecules (exp. 1.3), and a blank experiment without any deposition (exp. 1.4). The formation of H₂CO in CH₃OH+H is further verified using ¹³C-labelled methanol.

2) Verification of COM formation via radical–radical interactions in the aforementioned system; exps 2.1–2.8.

The hydrogenation experiments described in the previous section are further extended by performing codeposition experiments of binary ice mixtures, H₂CO+CO, CH₃OH+CO and H₂CO+CH₃OH with H-atoms. In the next section, it is shown that, for these experiments, COMs can be detected, specifically methyl formate (HC(O)OCH₃), glycolaldehyde (HC(O)CH₂OH) and ethylene glycol (H₂C(OH)CH₂OH). TPD QMS is used as the main diagnostic tool to detect these COMs because of (significant) spectral overlap of the stronger vibrational modes with H₂CO and CH₃OH infrared absorption features (Öberg et al. 2009).

3) The final set of TPD QMS experiments (exps 3.1–3.3) is specifically designed to rule out the possibility that any COMs are found due to contaminations in the depositing gas samples or as a result of thermally induced reactions during TPD. For this purpose, a series of depositions with mixed H₂CO:CH₃OH ices is followed by a regular TPD QMS experiment without any H atoms impacting. In these control experiments, the used H₂CO:CH₃OH ratios are chosen to cover the entire range of values as obtained in the hydrogenation experiments after 6 h of codeposition. This allows for a systematic comparison between the TPD QMS peak intensities of HC(O)OCH₃, HC(O)CH₂OH and H₂C(OH)CH₂OH found in the hydrogenation experiments and the corresponding results from the control experiments.

3 RESULTS

3.1 CO formation upon codeposition of H and H₂CO

In Fig. 1, RAIRS data (exps 1.1 and 1.2) for a 15 K codeposition experiment of H₂CO+H (upper spectrum) and only H₂CO (lower spectrum), i.e. without hydrogenation, are presented. The spectral signatures of the originally deposited H₂CO are found around 1727 cm⁻¹ as well as at 1499 and 1253 cm⁻¹; an H₂CO band around 1178 cm⁻¹ is harder to discriminate. In the H-atom addition experiment, new peaks at 1031 and 1423 cm⁻¹ can be assigned to the C–O stretching and O–H bending vibrational modes of CH₃OH, respectively (Falk & Whalley 1961). A clearly visible peak at 2138 cm⁻¹ is due to the stretching mode of CO. The formation of CH₃OH is

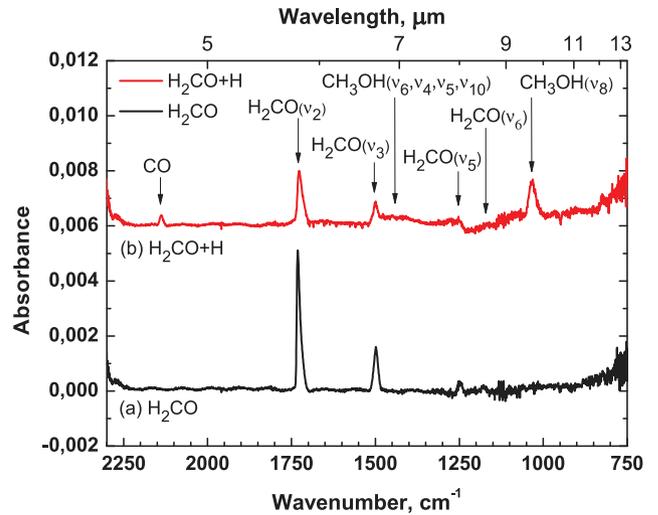

Figure 1. RAIR spectra obtained after 360 min (co)deposition at 15 K of (a) H₂CO and (b) H₂CO with H-atoms in a ratio H₂CO:H = 1:30 and an H-atom flux of 6×10^{14} atoms min⁻¹ cm⁻².

consistent with previous studies of successive hydrogenation of CO and H₂CO (Hiraoka et al. 1994; Watanabe & Kouchi 2002; Hidaka et al. 2004; Fuchs et al. 2009). The simultaneous appearance of the 2138 cm⁻¹ band indicates that along with the H-atom addition reactions to formaldehyde, resulting in the formation of CH₃OH, also a sequence of two H-atom abstraction reactions takes place, yielding CO. Spectral features of the intermediate radicals, i.e., HCO and CH₃O/CH₂OH are not observed, consistent with previous studies concluding that their abundance is low. This is due to the higher reactivity of these intermediates to H-atoms via barrierless reactions compared to the stable species that have to bypass activation barriers (Watanabe & Kouchi 2002; Fuchs et al. 2009).

The main experimental finding here is that interaction of H-atoms with H₂CO molecules at 15 K not only leads to the formation of methanol but also of carbon monoxide. This is in agreement with the experimental findings of Hidaka et al. (2004).

3.2 H₂CO formation upon codeposition of H and CH₃OH

The results of a CH₃OH+H 15 K codeposition experiment as well as reference data obtained for a pure CH₃OH deposition (exps 1.5 and 1.6) are shown in Fig. 2. In the left-hand panel, the wavelength domain that covers the strongest (RAIR) absorption band of H₂CO, i.e. its C–O stretching vibration mode, is shown (see also Fig. 1); neither this band nor any other H₂CO features can be found. The left shoulder of a broad band around 1652 cm⁻¹ could be due to the C–O stretching mode of formaldehyde, but given the absence of the other H₂CO bands the full absorption feature is more likely due to polluting H₂O that results from contamination in the H-atom beam. A similar band is also present in Fig. 1, but hard to see given the less accurate intensity scale used there.

More sensitive TPD QMS data are presented in the right-hand panel of Fig. 2, which confirm H₂CO formation. The two strongest *m/z* signals of H₂CO, i.e., HCO⁺ (29 amu) and H₂CO⁺ (30 amu) exhibit both a peak centred at 95 K. This desorption temperature as well as the *m/z* = 30 to *m/z* = 29 ratio of 0.6 are consistent with

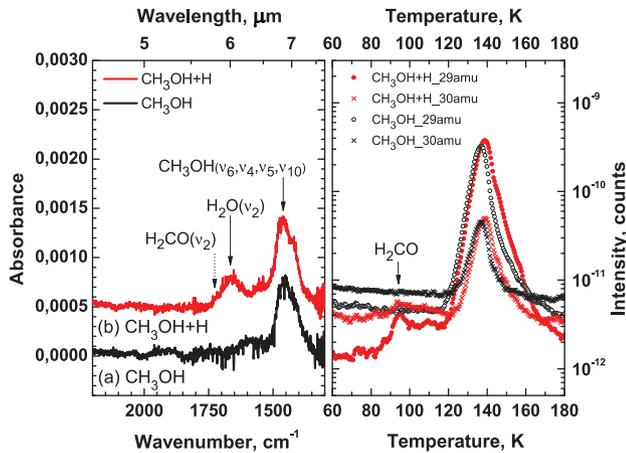

Figure 2. The left-hand panel shows RAIR spectra of 360 min (co)deposition at 15 K of (a) CH_3OH and (b) CH_3OH with H-atoms in a ratio $\text{CH}_3\text{OH}:\text{H} = 1:30$ and an H-atom flux of 6×10^{14} atoms cm^{-2} . The shown wavelength domain corresponds to the region where the strongest absorption features of H_2CO should be visible. The right-hand panel presents parts of the TPD QMS spectra obtained after these two experiments for $m/z = 29$ and 30 amu. Peaks at $T \sim 95$ and 140 K correspond to formaldehyde and methanol desorption, respectively.

literature data (Fuchs et al. 2009, NIST database¹). To further constrain H_2CO formation from $\text{H} + \text{CH}_3\text{OH}$, the experiment is repeated for ^{13}C -labelled methanol (not shown in Fig. 2). The TPD QMS shows the same peak at 95 K, but this time the maximum has an m/z value of 30 (as opposed to 29 for the regular ^{12}C isotope of H_2CO) and again a ratio of $m/z = 31$ to $m/z = 30$ of 0.6 is found. This is fully consistent with the conclusion that the species desorbing at 95 K can be assigned to formaldehyde and that it forms through hydrogen abstraction from CH_3OH . This means that the network derived by Hidaka et al. (2009) can be further extended to include a two-step dehydrogenation process transferring CH_3OH into H_2CO . Also here, the intermediate CH_2OH radical is not observed because of its high reactivity.

3.3 Formation of COMs: methyl formate, glycolaldehyde and ethylene glycol

In Fig. 3, the TPD QMS spectra (exps 1.1 and 1.2) are presented for a temperature range from 15 to 225 K taken after 360 min of $\text{H}_2\text{CO} + \text{H}$ codeposition and H_2CO deposition at 15 K, respectively. In addition to the desorption peaks from the originally deposited H_2CO , its hydrogenation product CH_3OH and its abstraction product CO (not shown), there are three more desorption peaks showing up. The TPD QMS spectra provide two ways to identify the desorbing species; via their desorption temperature and via their dissociative ionization fragmentation pattern upon electron impact in the head of the QMS. The first sublimation peak is centred at 120 K, the centre of the second one is located around 160 K, and the last one is around 200 K. Based on available data reported by Öberg et al. (2009) and recent work by Fedoseev et al. (2015), the aforementioned three desorption temperatures can be attributed to methyl formate, glycolaldehyde, and ethylene glycol, respectively.

¹ NIST Mass Spec Data Center, S.E. Stein, director, “Mass Spectra” in NIST Chemistry WebBook, NIST Standard Reference Database Number 69, Eds. P.J. Linstrom and W.G. Mallard, National Institute of Standards and Technology, Gaithersburg MD, 20899, <http://webbook.nist.gov>.

The assignments are further supported by the fragmentation patterns that are largely in agreement with the 70 eV patterns as available from the NIST database (see footnote 1). Relatively small inconsistencies in these patterns are likely due to the thermal codeposition of trapped H_2CO or CH_3OH with the aforementioned COMs, which have the same m/z values for some of the dissociative ionization fragments.

As mentioned before, these COMs could not be detected unambiguously by means of RAIRS, because there exists considerable overlap between the strongest IR absorption features of methyl formate, glycolaldehyde, and ethylene glycol with those of H_2CO and CH_3OH that have higher abundances in the ice. Furthermore, an attempt to detect these COMs through the molecule specific but weaker C–C stretching mode of glycolaldehyde and ethylene glycol or the O–CH₃ stretching mode of methyl formate were unsuccessful due to the low final yield of these species. Nevertheless, important information can be derived from spectroscopic data. Fig. 4 presents RAIR spectra obtained at 15 K after 850 min of H_2CO hydrogenation with excess of atomic hydrogen in a $\text{H}_2\text{CO}:\text{H} = 1:30$ ratio and compared with the results from an experiment in which H_2CO and CH_3OH are deposited in a 1:1 ratio (exps 1.11 and 2.6). The two left-hand panels show zoom-ins of wavelength domains that cover the strongest absorption features of HCO and CH_2OH . The two right-hand panels coincide with the strongest absorption features of glycolaldehyde. Moreover, a RAIR spectrum obtained after 1ML deposition of pure glycolaldehyde, as reported by Öberg et al. (2009), is included for a direct comparison. From this, it becomes clear that while the strongest absorption features of HCO and CH_2OH cannot be seen (left-hand panel), those of $\text{HC(O)CH}_2\text{OH}$ can be observed in the ice, despite substantial overlap with H_2CO and CH_3OH features. For example, the ~ 1748 cm^{-1} peak of glycolaldehyde is positively identified in the left shoulder of the $\text{H}_2\text{CO}(\nu_2)$ band obtained after codeposition of H_2CO with H-atoms, since this absorption band is not present in the spectra of pure $\text{H}_2\text{CO}:\text{CH}_3\text{OH}$ ice mixtures. Similarly, no contradiction is found with the possible presence of the ~ 1112 cm^{-1} absorbance feature of $\text{HC(O)CH}_2\text{OH}$ on the spectrum obtained in the $\text{H}_2\text{CO} + \text{H}$ experiment. This provides a strong argument that glycolaldehyde is formed already at 15 K among other products in a $\text{H}_2\text{CO} + \text{H}$ codeposition experiment, and that detection of COMs during the TPD by means of the QMS is not the result of recombination of radicals trapped in the lattice of the ice at higher temperatures.

Furthermore, repeating the H_2CO codeposition with H-atoms at higher temperatures, i.e. at 25 and 50 K, does not result in COM detections. This is not surprising since the H-atom lifetime on the surface drops significantly at higher temperatures, which results in a drastic decrease of reactivity of H_2CO with H-atoms at 25 K and a complete inhibition at 50 K. A similar decrease of reaction rates with temperature was observed by Fuchs et al. (2009) and Hidaka, Kouchi & Watanabe (2007) upon CO hydrogenation.

3.4 Establishing the types of involved intermediate radicals

In an attempt to reveal in more detail the reaction mechanisms responsible for the formation of methyl formate, glycolaldehyde and ethylene glycol, several additional experiments are performed. Since different kinds of intermediate radicals are formed upon H-atom exposure of CO and CH_3OH , i.e. HCO and possibly CH_2OH (Nagaoka, Watanabe & Kouchi 2007), two-component binary mixtures of CO with H_2CO , CO with CH_3OH , and H_2CO with CH_3OH are codeposited with H-atoms at 15 K (exps 2.1, 2.3 and 2.5). Subsequently, relative COM abundances are examined in each of the

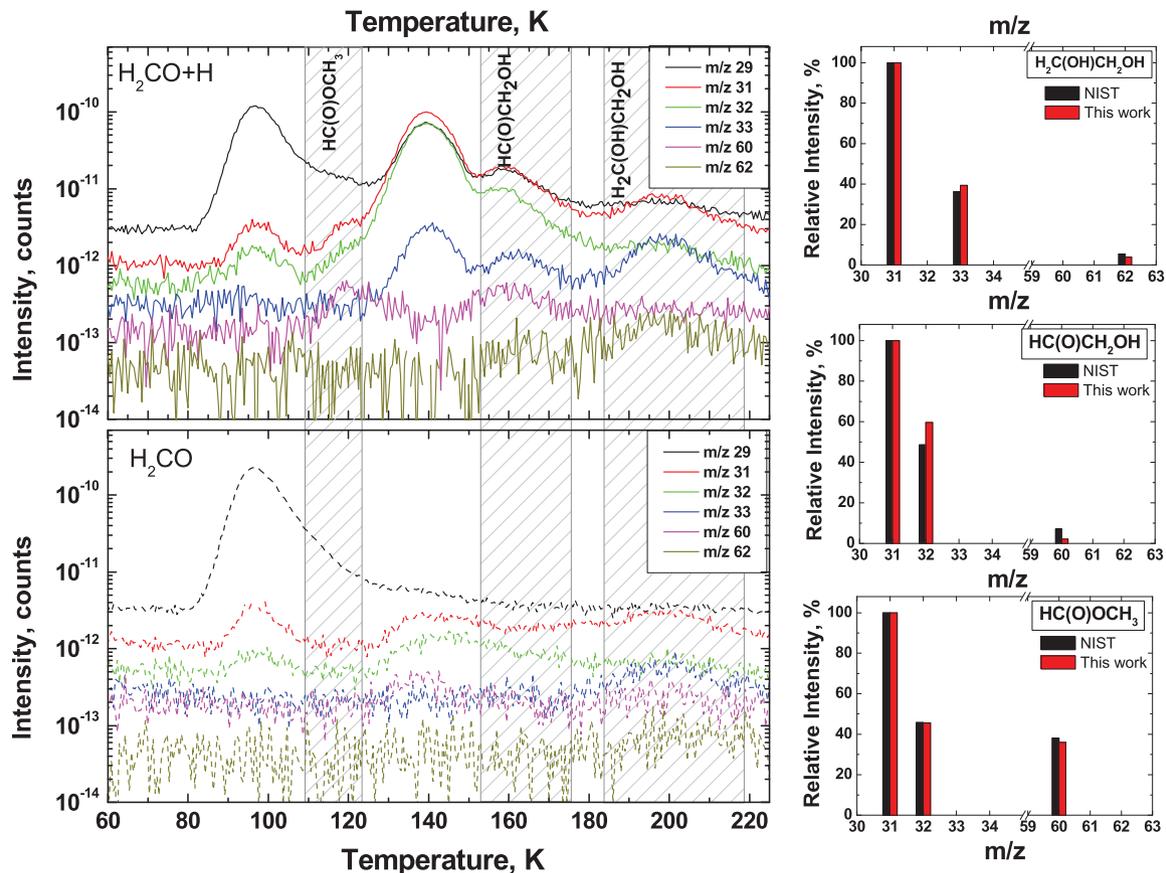

Figure 3. Left: the TPD mass spectra obtained after deposition of H₂CO (lower panel) and equal amounts of H₂CO and H-atoms (upper panel). The codepositions are performed at 15 K for 360 min, using a mixture of H₂CO:H = 1:30 and an H-atom flux equal to 6×10^{14} atoms $\text{min}^{-1} \text{cm}^{-2}$. Only relevant m/z numbers are shown. Right: comparison of the fragmentation patterns of the detected desorbing COMs with available literature values.

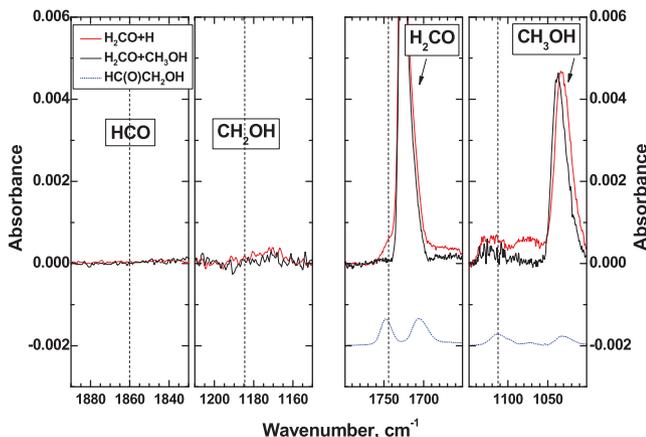

Figure 4. RAIR spectra obtained after codeposition of H₂CO and H-atoms for 850 min at 15 K using a ratio H₂CO:H = 1:30 (exp. 1.11) and codeposition of H₂CO with CH₃OH using a 1:1 ratio (exp. 2.6). The two left-hand panels show the regions of the spectra where the most intense absorption features of HCO and CH₂OH are expected. The two right-hand panels show the spectral regions where the strongest absorption features from HC(O)CH₂OH are present, scaled for the amount of H₂CO and CH₃OH, respectively. A spectrum of pure HC(O)CH₂OH (blue) is presented for comparison.

experiments (see Table 1). To facilitate direct comparisons among these experiments, a 1:1 ratio is used for the molecular constituents, while the total applied ratio, including H-atoms, amounts to 1:1:30 to guarantee that (de)hydrogenation effects will be clearly visible.

The formation of all three COMs is observed in each of the experiments with the exception of CO+CH₃OH+H, where methyl formate cannot be detected. Fig. 5 shows the comparison between the H₂CO+H and CO+CH₃OH+H experiments for selected TPD QMS spectra and the relevant m/z values. In the H₂CO+H codeposition (left-hand panel), a desorption peak centred around 120 K is clearly seen and assigned to HC(O)OCH₃ according to the QMS fragmentation shown in Fig. 3. However, in the CO+CH₃OH+H ice mixture experiment (right-hand panel), there are no mass signals that can be assigned to methyl formate. This is an important finding which shows that only the abundant presence of H₂CO in the sample produces HC(O)OCH₃ molecules. Although some amount of H₂CO can be formed in the CO+CH₃OH+H experiment by hydrogenation of CO molecules and by dehydrogenation of CH₃OH (see signal 29 m/z at ~ 96 K in Fig. 5), this is not effective enough for our experimental settings to be transformed to a detectable amount of HC(O)OCH₃.

3.5 Control experiments

H₂CO is sensitive to its ice surrounding, and is chemically active upon thermal processing, when embedded in an H₂O, CH₃OH, and/or NH₃ environment (Schutte, Allamandola & Sandford 1993; Duvernay et al. 2014). Also, despite cleaning procedures, low-level pollutions may be involved that influence final outcomes. Therefore, in order to exclude any artefacts, three control experiments (exps 3.1–3.3) involving the deposition of different H₂CO:CH₃OH ice mixtures (CH₃OH/H₂CO ratio = 0.1, 0.3 and

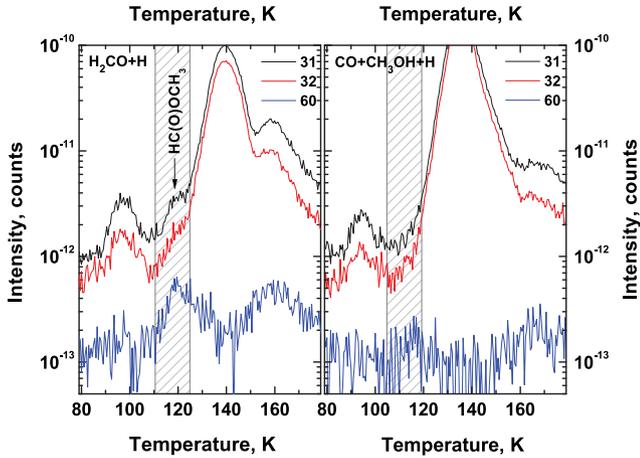

Figure 5. Left: the TPD QMS spectrum obtained after codeposition of H₂CO with H-atoms at 15 K for 360 min with H₂CO:H = 1:30. Right: TPD QMS spectrum obtained after codeposition of CO, CH₃OH and H-atoms with CO:CH₃OH:H = 1:1:30 for the same experimental conditions. The H-atom flux in both experiments is equal to 6×10^{14} atoms min⁻¹ cm⁻². Only selected *m/z* values from the desorbing species are indicated. The desorption peak centred around 120 K and assigned to HC(O)OCH₃ is visible in the left-hand panel, while it is absent among the products of the experiment shown in the right-hand panel. The 140 and 160 K peaks are due to methanol and glycolaldehyde, respectively.

3.5) are performed and TPD QMS spectra are acquired. In Fig. 6, the normalized integrated QMS signals are shown for each of the three COMs found here and for each of the used mixing rates. In the same figure, also the COM intensities are plotted as obtained in our hydrogenation experiments versus the final H₂CO and CH₃OH abundance ratio obtained after 6 h of codeposition. It should be noted that the ethylene glycol, glycolaldehyde and methyl formate abundances presented in Fig. 6 are normalized with respect to the total amount of H₂CO and CH₃OH observed by RAIRS at the end of a codeposition experiment but before starting a TPD QMS experiment. The error bars represent instrumental errors and do not account for uncertainties resulting from the baseline subtraction procedure. The CO abundance is not taken into account here due to the expected chemical inertness of this species during thermal processing.

The comparison between hydrogenation and control experiments indicates that COMs are formed in the ice and cold surface H-atom addition and abstraction reactions are required to explain the observed COM abundances because the relative intensity of the newly formed COMs generally exceeds the one from the control experiments. However, there are some observations that need to be pointed out. For instance, in the case of H₂C(OH)CH₂OH (top panel of Fig. 6), some H₂C(OH)CH₂OH is present in the control experiments and a clear growing trend with increasing CH₃OH is observed and fitted with a polynomial function. This can be explained by either the presence of ethylene glycol as a contamination in the CH₃OH sample or by thermally induced chemistry involving CH₃OH molecules. However, the intensity of the observed H₂C(OH)CH₂OH produced by hydrogenation is significantly higher than that found in the control experiments for all hydrogenated ice mixtures except that with the highest CH₃OH abundance (exp. 2.3). For both HC(O)CH₂OH and HC(O)OCH₃ molecules (middle and bottom panels of Fig. 6), the observed intensities in the hydrogenation experiments cannot be reproduced in the control experiments, with the exception of the CO+CH₃OH+H and CO+H co-deposition experiments (exps

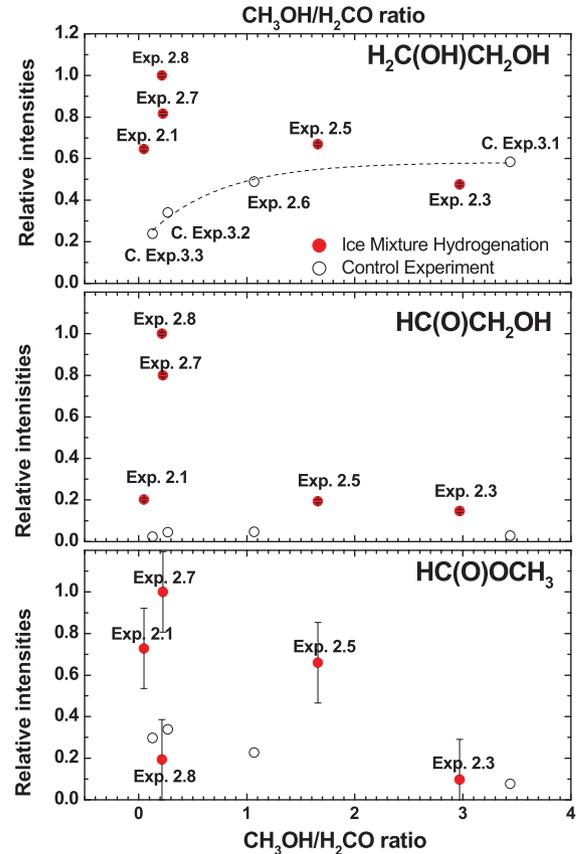

Figure 6. Normalized integrated TPD QMS intensities for each of the three COMs discussed here (upper panel = ethylene glycol, middle panel = glycolaldehyde and lower panel = methyl formate) as a function of the CH₃OH/H₂CO mixing ratio. The empty circles indicate the results of the control experiments, i.e. without hydrogenation. Solid circles show the result from the ice mixture hydrogenation experiments. The mass peaks used for the integration are *m/z* = 31, 31 and 60 for upper, middle and lower panel, respectively. The numbers are normalized with respect to the total amount of H₂CO and CH₃OH observed before the TPD experiment.

2.3 and 2.8), where the abundance of HC(O)OCH₃ is lower than the value obtained in the control experiments at the corresponding CH₃OH/H₂CO ratio.

To further understand the relative abundance of the produced COMs in all the performed experiments, the final COM abundances obtained after each experiment is normalized to the total amount of deposited carbon-bearing species, i.e., CO, H₂CO and CH₃OH. Results are presented in Fig. 7 (black columns). Since a non-negligible amount of H₂C(OH)CH₂OH is observed in all the control experiments (top panel of Fig. 6), this has been taken into account and subtracted from the final H₂C(OH)CH₂OH abundances observed in the hydrogenation experiments using a procedure described below. The control experiment data points (upper panel of Fig. 6) are fitted with the polynomial function. Subsequently, the obtained coefficients – ‘H₂C(OH)CH₂OH_(control exp.)’/‘H₂C(OH)CH₂OH_(hydrogenation exp.)’ – are derived for all of the hydrogenation experiment data points. Consequently, the H₂C(OH)CH₂OH abundances are reduced by the obtained coefficients and presented in Fig. 7 (red columns in top panel of Fig. 7). The latter should be treated as a relative comparison of the lower formation limits of the observed COMs.

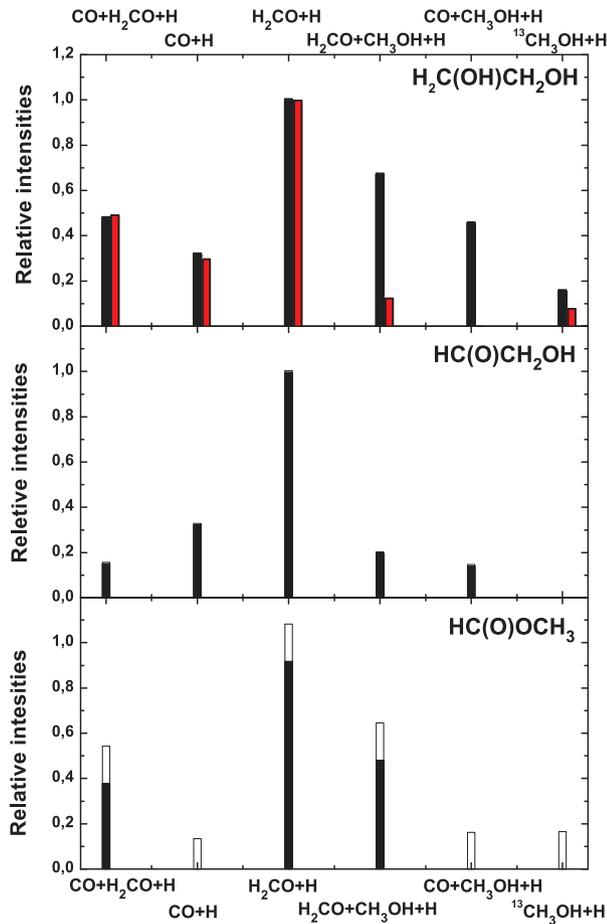

Figure 7. Relative comparison of the integrated intensities of ethylene glycol (upper panel), glycolaldehyde (middle panel), and methyl formate (lower panel) observed by means of TPD QMS and normalized for the total amount of carbon-bearing molecules observed before performing the TPD experiment. Black columns represent raw data. In the upper panel, red columns represent the data obtained after reduction of the control experiments shown in Fig. 6 and should be treated as relative comparison of the lower formation limits observed in this study. White bars (mainly visible in the lower panel, but present in all the panels) represent instrumental errors.

4 DISCUSSION

4.1 Chemical network

As described by Fedoseev et al. (2015), the formation COMs observed here can be explained by interaction of intermediate radicals that are formed upon H-atom addition and abstraction reactions with H₂CO. These are CH₃O and possibly CH₂OH radicals formed in the reaction:

which then further yield methanol through the reaction:

and HCO radicals formed through the reaction:

which is a necessary step to form CO through the reaction:

Various reactions involving these intermediate radicals can directly yield glycolaldehyde and ethylene glycol following reaction (1b):

or methyl formate in case of reaction (1a):

This scheme is also fully consistent with the formation route of ethylene glycol and glycolaldehyde through the sequence of reactions involving glyoxal proposed by Fedoseev et al. (2015):

The presence of methyl formate among the products observed in this study indicates that reaction (1a,b) should at least partially result in the formation of CH₃O (instead of CH₂OH) to yield HC(O)OCH₃ through reaction (7). Methyl formate was not observed by Fedoseev et al. (2015); the use of CO as a starting point in that study resulted in considerably lower final yields of H₂CO and CH₃OH than in this work and, therefore, significantly lower amounts of formed CH₃O than required to yield methyl formate.

Interaction of H₂CO molecules with H-atoms results in both the formation of HCO and CH₃O radicals via H-atom abstraction and addition, respectively. The latter process can also lead to the formation of CH₂OH radicals in the case that the H-atom addition takes place on the oxygen side of the H₂CO molecule. The non-detection of HC(O)OCH₃ among the detected COMs in CO+CH₃OH+H implies that one of these radicals must play a crucial role in the formation of methyl formate. This cannot be HCO, as it can be produced by H-atom additions to CO molecules present in the ice mixture, thus it must be a reaction product of H-atom additions to H₂CO. Taking into account reaction (7), which describes HC(O)OCH₃ formation, this radical should be CH₃O. This, in turn, allows drawing an important conclusion: H-atom abstraction reactions from CH₃OH do not result in efficient formation of CH₃O radicals but yield primarily CH₂OH:

as otherwise the presence of H₂CO would not be a pre-requisite.

This conclusion is consistent with the result of Nagaoka et al. (2007) and Hidaka et al. (2009) obtained by studying deuterium substitution in methanol. Furthermore, H-atom addition reactions to H₂CO should result in considerable amounts of formed CH₃O through reaction (1), while the formation of CH₂OH in this reaction is expected to be a less efficient process.

The non-production of glycolaldehyde in the CO+CH₃OH+H codeposition experiment (exp. 2.3) obtained after subtraction of the control experiment data should be stressed here. This suggests that the H₂C(OH)CH₂OH formation mechanism through reactions (11)

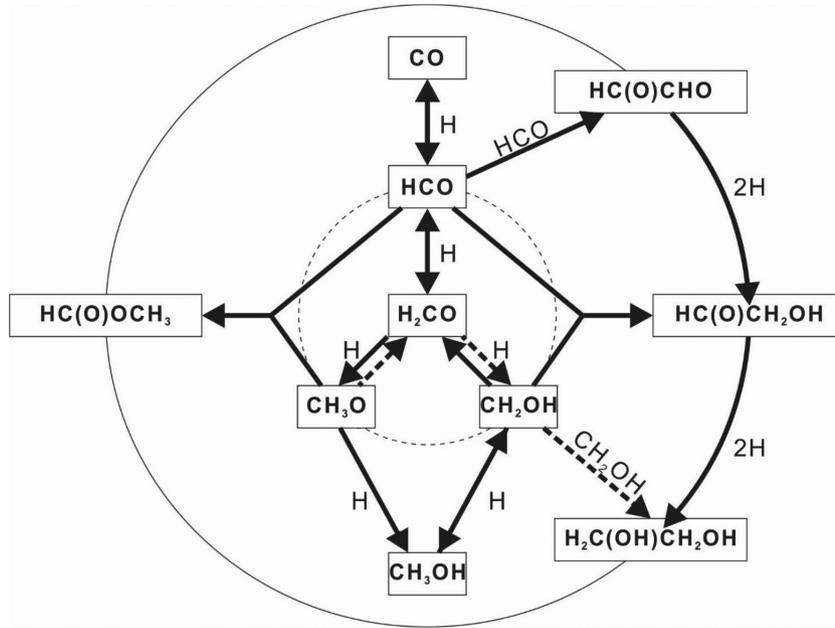

Figure 8. Extended COM formation network as obtained from the CO, H₂CO, and CH₃OH hydrogenation experiments. Solid arrows indicate the reaction pathways confirmed or suggested in this study. Dashed lines indicate the overall less efficient pathways.

and (6) is overall less efficient than through reactions (5) and (10) or reactions (8)–(10). This may be an indication of a lower formation rate of CH₂OH in reaction (11) compared to the HCO formation rates in CO + H or in reaction (3).

Another reason why recombination of CH₂OH radicals to yield H₂C(OH)CH₂OH seems overall less efficient than recombination of HCO with HCO, CH₃O or CH₂OH radicals may be due to a geometrical properties of the species involved. The access to the unpaired electron of CH₂OH radical is significantly blocked by H-atoms bonded to carbon and oxygen atoms, while in the case of HCO radical the access to the unpaired electron will be easier. Thus, one can expect that the rate of CH₂OH radical recombination is less probable, or, alternatively, results in H-atom abstraction to form methanol and formaldehyde:

due to the easier access of H-atoms to C-H bonds.

The proposed COM formation network based on all investigated reaction routes is presented in Fig. 8. From top to bottom, a chain of H-atom addition and abstraction reactions leading to the formation of CH₃OH from CO is shown. As confirmed in this study, H₂CO can undergo an abstraction reaction induced by H-atoms to form HCO radicals, which successively can be dehydrogenated to form simple molecules, i.e. CO, thus increasing the total number of HCO formation events and its lifetime in the ice mantle. H₂CO also participates in addition reactions with H-atoms. Formation of the CH₃O radical is confirmed in this study by observing methyl formate; however, formation of CH₂OH radicals cannot be excluded, since all experiments involving H₂CO codeposition demonstrate relatively high yields of glycolaldehyde and ethylene glycol. In contrast, H-atom-induced abstraction reaction involving CH₃OH likely yield CH₂OH while no proof for CH₃O formation is found.

The barrier-less recombination of HCO intermediates yielding glyoxal followed by consequent hydrogenation, i.e. the mechanism investigated in Fedoseev et al. 2015, yields HC(O)CH₂OH and H₂C(OH)CH₂OH and is presented in the right-hand panel

of the diagram. Alternatively, the intermediate HCO radicals can directly recombine with CH₃O or CH₂OH to form HC(O)OCH₃ and HC(O)CH₂OH, respectively. CH₂OH and CH₂OH recombination (dash arrows) seems to contribute less to the formation of H₂C(OH)CH₂OH. This may be explained by geometrical constraints or overall low efficiencies of abstraction reactions involving methanol.

From our experimental results, we cannot confidently determine whether diffusion of the intermediate radicals is involved in the formation of the observed methyl formate, ethylene glycol and glycolaldehyde at 15 K. In the simulations reported by Fedoseev et al. (2015), high activation barriers are used for HCO and CH₃O diffusion. This effectively immobilizes such species and only radicals formed next to each can recombine. Fedoseev et al. (2015) showed that the formation and reaction of adjacent radicals explains the observed results, offering an efficient formation pathway even at the low temperatures typical for dense dark clouds (~10 K). This is consistent with the laboratory detection of the three COMs discussed here. It should be noted that a similar reasoning is often used to explain results obtained in photoprocessing experiments, i.e. two consequent photodissociation events result in the formation of radicals that can recombine when located next to each other in the bulk of the ice (Öberg et al. 2009).

Another mechanism that may be important is the diffusion of newly formed intermediate radicals upon exothermic formation. The involved excess energy supports the diffusion of molecules and radicals even at low temperature. Radicals produced upon photodissociation in the ice initially have excess energy and can diffuse, as demonstrated by molecular dynamics simulations (*e.g.* Andersson et al. 2006). From our measurements, the impact of this process cannot be confirmed.

4.2 Astrochemical implications and conclusions

In dense molecular clouds, the reaction between CO molecules and H-atoms accreting on the grain surface does not only explain the

abundance of interstellar methanol (Watanabe et al. 2006; Cuppen et al. 2009), but also its deuterium enrichment (Nagaoka et al. 2005; Hidaka et al. 2009). The latter can be realized through the series of H-atom abstraction reactions from the C-H ends of H₂CO and CH₃OH followed by D-atom additions, which take place faster than the corresponding D-atom abstraction reactions followed by substitution with H-atoms. HCO and CH₂OH are possible intermediates in these H-atom abstraction reactions.

In this work, we confirm that such H-atom-induced abstraction reactions take place by experimental observations of H₂CO formation upon H-atom exposure of CH₃OH and CO formation upon H-atom exposure of H₂CO for an astronomically relevant temperature of 15 K. This means that a CO hydrogenation mechanism leading to the formation of interstellar methanol in dark molecular clouds is not irreversible. CH₃OH as well as its formation intermediates can participate in sequences of consecutive H-atom addition and abstraction reactions, thus, once formed, H₂CO and CH₃OH molecules can be potentially dehydrogenated and become once again available for hydrogenation.

Interactions between reactive radicals such as those produced here are actively discussed in the literature as a source for COM formation, both theoretically and experimentally (Hudson & Moore, 2000; Bennett et al. 2007; Garrod et al. 2008; Öberg et al. 2009; Woods et al. 2012; Garrod 2013). In these models, UV photon or cosmic-ray-induced dissociation of CH₃OH is usually taken as the external trigger responsible for the formation of these various intermediates. However, Fedoseev et al. (2015) experimentally showed that glycolaldehyde (HC(O)CH₂OH) and ethylene glycol (H₂C(OH)CH₂OH) can be equally efficiently formed just by cold surface hydrogenation of CO molecules without involvement of UV- or cosmic-ray energetic processing of interstellar ices at 15 K. Here, we report that in addition to glycolaldehyde and ethylene glycol formation also methyl formate (HC(O)OCH₃) production is observed. The suggested mechanism of HC(O)OCH₃ formation is the radical–radical recombination of HCO, formed either by H-atom addition to a CO molecule or H-atom abstraction from H₂CO, and CH₃O produced by H-atom addition to H₂CO. Furthermore, along with the formation of glycolaldehyde and ethylene glycol through the recombination of HCO radicals and the subsequent hydrogenation of glyoxal (Woods et al. 2013; Fedoseev et al. 2015), glycolaldehyde can be formed through the direct recombination of HCO and CH₂OH radicals, while ethylene glycol can form through the recombination of two CH₂OH radicals. However, the latter radical-radical reaction is found to be less efficient than the hydrogenation of glycolaldehyde under our experimental conditions.

Codeposition of H₂CO with H-atoms at 25 and 50 K results in a decrease of the efficiency of both abstraction and addition reactions; consequently, no formation of COMs is observed at these temperatures. This can be explained by a substantial drop in the life-time of H-atoms on the ice surface with increase of the temperature.

The direct consequence of both H-atom addition and abstraction reactions is to increase the number of interaction events as well as the timespan over which radicals reside in the ice. This should increase the overall reactivity and likely more COMs are formed through recombination of reactive intermediates than assumed so far. Clearly, the seemingly opposite processes of H-atom addition and abstraction reactions will decrease the overall efficiency to form methanol directly from CO hydrogenation, essentially shifting the equilibrium point. The rates inferred by Fuchs et al. (2009) should therefore, be regarded as effective rates. In parallel, other processes become possible, increasing the overall efficiency with

which COMs are formed. This process that is studied here only for a few temperature settings, is expected to be temperature dependent.

The main take-home message from this work is that addition and abstraction reactions upon H-atom exposure of ice mantles can explain the formation of COMs in dense molecular clouds even when energetic external UV radiation or cosmic rays are lacking. It also means that solid state COM formation can start already at the beginning of the CO freeze-out stage, well before CH₃OH containing ices are thermally and energetically processed by the heating and radiation of the emerging protostar. It should be mentioned, that diffusion related processes will be different for the long astrochemical time-scales at play and can enhance the overall efficiency in comparison with the short laboratory time-scales. This provides further support of the COM formation mechanisms discussed in this work. This has important implications in astrobiology; glycolaldehyde is the simplest representative of the aldoses family to which sugars like glucose, ribose and erythrose belong, while ethylene glycol is the simplest polyol among which the triol glycerin is well known. As such, the non-energetic processes discussed here provide an important alternative to the formation of these pre-biotically relevant species at an early stage in the chemical evolution of dark interstellar clouds.

The recent gas phase detection of COMs in pre-stellar cores, i.e., environments where temperatures are too low to initiate thermal desorption, raises questions concerning the efficiency of solid state formation of complex molecules and the process(es) responsible for their desorption. Typically, non-thermal desorption mechanisms, that is, upon impacting cosmic rays or irradiation by secondary UV photons, are expected to explain the effective transfer from solid state to gas phase (Bacmann et al. 2012; Cernicharo et al. 2012). In the case of CO, non-dissociative photodesorption explains the observed gas phase abundances (Fayolle et al. 2011), but for other species, like methanol, photodissociation seems to offer a competing scenario, (Öberg et al. 2009). However, larger species may be able to dissipate excess energy more effectively, due to the larger amount of vibrational modes that will help decreasing the dissociation efficiency. Another desorption mechanism that may be relevant is through cosmic ray induced impulsive spot heating. This process has been described in detail by Ivlev et al. (2015). The model presented by Garrod, Wakelam & Herbst (2007) shows that chemisorption offers another alternative mechanism; excess energy due to exothermicity of surface reactions offers a low temperature non-thermal desorption pathway. It is possible, given the nature of the reactions discussed in this work that COMs formed in CO-rich ices experience chemisorption. Moreover, intermolecular (van der Waals like) interactions with CO will be weak, compared to hydrogen bonds in water rich ices. At the moment, the nature of the process bridging the grain–gas gap is still unclear, and the work presented here offers good arguments for a further focus in future studies.
